Abstract

Much research has been carried out to manage structured documents such as SGML (Standard Generalized Markup Language) or XML (eXtensible Markup Language) documents and to provide powerful query facilities exploiting document content, structure, and attributes. In order to perform structure queries efficiently on structured documents, a good indexing method for structured documents is important and necessary. In this paper, we present an indexing method which is utilized for supporting efficient query on content, structure and attributes on XML documents. Furthermore, we propose some strategies of update method to maintain the integration of changed index information and original XML documents.

Keywords: structure query, index method, DOM parser, structured document, and XML

1 Introduction

Structured documents are the documents that embed the document structures into the texts. Recently, many documents tend to be produced as structured ones using markup languages like SGML or XML since they make it possible to handle the texts in piece by piece in browsing or retrieval. Assume that the documents have been originally supplied with tagged in SGML. Furthermore, World Wide Web is likely to step toward XML from HTML (HyperText Markup Language) soon in creating Web pages. SGML and XML provide full-fledged features in making documents structured as they are, whereas HTML has only limited functions in structuring.

This tendency calls for the emergency of a new information retrieval system that enables to retrieve and access arbitrary parts of documents easily. It raises a difficult problem that the system should be able to figure out relevant elements to users queries issued at any level of the structure, which have not been tackled seriously in the conventional information retrieval system. And most of the structuring techniques proposed so far did not handle the problem efficiently.

In this paper, we propose an indexing method for supporting query on content, structure and attributes on XML documents that minimizes the indexing overhead and guarantees fast query response time. The main idea is that indexing is performed by assign an index interval to every node while traversing the tree in preordering way. We build inverted lists for content, structure and attributes query on XML documents.
This paper is organized as followings. In Section 2 we describe some related works about indexing methods on structured documents, in Section 3 we discuss how to build the index information, modify the index interval method, and reduce the space overhead on index information to improve query efficiency and more query types. Section 4 is describing the update method to maintain the integration of index information and original XML documents after the structured documents had be inserted, deleted, or modified. In section 5, we discuss the works we are doing follows up this paper was published and some future works that can improve in the information retrieval system. Section 6 presents concluding remarks with the proposed concepts of this paper.

2 Related works

For years, there has been growing interest in handling structured documents well in terms of indexing and retrieval. In this section, we discuss some indexing methods for structured documents e.g. SGML or XML documents. First one is a kind of indexing methods on structured documents by using TEI (Text Encoding for Interchange) guidelines – an encoding standard adopted by the humanities disciplines. Second one is uses an $m$-ary complete tree structure to create a document tree and assign a UID for each node of tree structure according to the order of the level-order tree traversal in subsection 2.2. In subsection 2.3, a method uses the index interval concept to assign each node the step numbers for reaching and leaving the node while traversing by the preorder way.

2.1 Indexing with TEI guidelines

Tuong Dao [6] encodes the structured document according to the TEI guidelines, and uses the extension of SCL (Simple Concordance Lists) model to support content, structure, and attribute queries on structured document. But, this method does not use the concept of tree structure to handle the index information. It uses containment relationships rather than hierarchical relationships to support queries on document structure. The document in Figure 1 is the collection of English classic texts available for public use at the Oxford Text Archive which contains three divisions, the table of contents and two chapters. In Figure 1, structural elements are marked up with XML tags and encoded by TEI guidelines.

2.2 Indexing with UID

Lee et al. [7] proposed an indexing structure that is able to reduce the storage overhead taken to indexing at all levels of document structure. They first represented a document as an $m$-ary complete tree where $m$ is the largest number of child elements of an element in the structure. The result of the mapping is called ‘document tree’. Secondly they assigned each element a UID (Unique element IDentifier) according to the order of the level-order tree traversal. For example, the document tree in

---

**Figure 1:** Document in the text collection

---
Figure 2, we assign UID’s as shown in the Table 1 assuming a 3-ary tree. Here, we can consider this document tree as following: the node \( a \) is a book, \( b \) a chapter, \( d \) a section, and \( h \) is a subsection. Because they use the concept of complete tree, there are some virtual nodes which do not exist.

![Document Tree Diagram](image)

**Figure 2:** Example of document tree

<table>
<thead>
<tr>
<th>Element</th>
<th>UID</th>
<th>Element</th>
<th>UID</th>
</tr>
</thead>
<tbody>
<tr>
<td>( a )</td>
<td>1</td>
<td>( f )</td>
<td>8</td>
</tr>
<tr>
<td>( b )</td>
<td>2</td>
<td>( g )</td>
<td>9</td>
</tr>
<tr>
<td>( c )</td>
<td>3</td>
<td>( h )</td>
<td>14</td>
</tr>
<tr>
<td>( d )</td>
<td>5</td>
<td>( i )</td>
<td>15</td>
</tr>
<tr>
<td>( e )</td>
<td>6</td>
<td>( j )</td>
<td>16</td>
</tr>
</tbody>
</table>

The UID’s of the parent and \( j \)-th child of a node whose UID is \( i \) can be obtained by the following two functions. Using these functions we can only decide the parent-child relationship between two nodes on condition that the difference of their level numbers is just 1. If the condition doesn’t hold, the parent-child relationship has no choice to be decided by these two functions in recursive way.

\[
parent(i) = \left\lceil \frac{(i-2)}{k} + 1 \right\rceil \quad (1)
\]

\[
child(i, j) = k(i-1) + j + 1 \quad (2)
\]

### 2.3 Indexing with index interval

Jyh-Hong Tsay et al. [3] proposed an index method by using the index interval concept which assigns each node a pair of interval numbers - `<1st_index, 2nd_index>` according to the step numbers for reaching and leaving the node while traversing through the DOM tree in the preorder way. From this index interval concept, we can infer the relationship of parent-child in any level and the relationship of sibling in the same level by comparing the index interval numbers of specified nodes. They also proposed a document updating method – *Lazy update* by using the index update table to record the index update and index transformation information. This method lets the system does not need to update the index information immediately and could select suitable time to clean up the index table after the document is inserted, deleted, or modified. However, this method does not provide complete solution for inserting elements to the structured document and deleting elements from the structured document. Furthermore, they do not support the attribute query type for structured documents.

### 3 The indexing method

Indexing on structured documents for content, structure and attribute queries can be performed in various ways. In traditional text information retrieval systems, only the queries on content are supported. The rich structural information is contained in documents and the attributes of document components are not captured in these systems, and the queries on structure and attributes are not supported. For improving the index interval method [3] and adding the extra index information about the elements in XML documents, we use a kind of XML parser – DOM (Document Object Model) parser to build the index information and
propose five basic query functions to carry out the structure queries, provide information retrieval efficiently, and support more structure query types on structure documents.

3.1 Building the index information

The main idea of building the index information is that we use the DOM parser to parse the whole XML document into a tree structure, assign associated information (i.e. \(\text{index information} = \langle \text{document number; 1st_index, 2nd_index, level number} \rangle\)) to each node in preordering way, and save the index information into three kinds of index information lists according to the node types – the element node, the attribute node and the text node. The index information of all element nodes is recorded into the ELEMENT list, the index information and attribute values of all element attribute nodes are recorded into the ATTRIBUTE list and the index information and content of all text node are recorded into the TEXT list. The concept of this processing is shown in Figure 3.

![Figure 3: Building index information](image)

The two interval numbers (1st\_index and 2nd\_index) of index interval are the step numbers of reaching and leaving the node of the document tree while traversing in preorder way. This pair of index interval numbers could be used to determine what kind of relationships do specify nodes have by comparing the index interval numbers. We assume the two index interval numbers of nodes - \(U\) and \(V\) are \(U_{1st}\), \(U_{2nd}\) and \(V_{1st}\), \(V_{2nd}\) respectively. If \(V_{1st} < U_{1st}\), and \(U_{2nd} < V_{2nd}\), then the node \(U\) is a descendent of the node \(V\). If \(U_{1st} = V_{2nd} + 1\) or \(V_{1st} = U_{2nd} + 1\), then the node \(U\) is a sibling of the node \(V\).

The document number tells which document the element belongs to, and the level number informs which level the element belongs to. An example of an XML document and its tree structure are shown in Figure 4 and Figure 5 respectively.

![Figure 4: Example document](image)

After building the index information, according to the node type number we separate the index information into three lists – ELEMENT, ATTRIBUTE, and TEXT. In this processing phase, the system does not store the 2nd\_index and level number into ATTRIBUTE and TEXT lists. Moreover, the system adds the attribute values after the corresponding index
information of the attribute. The content of these lists are shown in Figure 6. There is an additional temporary list – Q-TEXT that is not stored in the storage. We can use TEXT list to figure out Q-TEXT list for answering query requirements after loading these three index information lists into the memory.

We will discuss the contents of these lists in following. In ELEMENT list, it contains the name of elements and its index information. If an element includes only one element, it could combine with its child element and keep the index information of its child. In this way, we can not only store the parent-child relationship of these two nodes but also save some storage spaces. In our example document, author and lastname elements are combined into one element – author/lastname and stored into ELEMENT list using the index information of lastname. The symbol “/” between author and lastname is used to show their parent-child relationship. The index information of TEXT list and Q-TEXT list just includes content of nodes, its document number and first index interval number. Because the second index interval number of TEXT nodes always equals to its first index interval number adds one. In this way, we not only reduce some space overhead but also infer the second index interval number of specific node from one’s first index interval number. In order to keep the attribute value of the attribute node, the ATTRIBUTE list includes the name of attribute and its index information – document number, first index interval number, and attribute value. In the ATTRIBUTE list, we just keep the first index interval number, because we can only use the first index interval number to decide which element node includes this attribute node.
3.2 Five basic query functions

The XML documents are marked up with start-tags and end-tags, these markup tags are used to delimit the boundaries of structural elements or specify the values of attributes associated with structural elements. Based on these properties of XML documents, we propose five basic query functions for finding out the index information and inferring relationships of specified elements, attributes, or keywords. The description of these basic query functions and the corresponding examples based on the previous example document are shown in Table 2.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Match_Text</td>
<td>Return the index information of the specified word or the word of the specified index information in a document. Return NULL, if not matched.</td>
<td>1) Match_Text (&quot;Darwen&quot;) Return: 1 35 2) Match_Text (1, 11) Return: Date</td>
</tr>
<tr>
<td>Match_Ele</td>
<td>Return the index information of the specified element in a document. Return NULL, if not matched.</td>
<td>Match_Ele (&quot;title&quot;) Return: 1 5 8 3 and 1 23 26 3</td>
</tr>
<tr>
<td>Include</td>
<td>Return index information of the specified element which includes the specified index information. Return NULL, if not found.</td>
<td>1) Include (&quot;publisher/name&quot;, 1, 41) Return: 1 40 43 4 2) Include (&quot;book&quot;, 1, 16, 19, 4) Return: 1 4 21 2</td>
</tr>
<tr>
<td>Included</td>
<td>Return index information of the specified element which is included in the specified index information. Return NULL, if not found.</td>
<td>Included (&quot;title&quot;, 1, 4, 21, 2) Return: 1 5 8 3</td>
</tr>
</tbody>
</table>

Table 2: The description and examples of basic query functions

3.3 Query on content, structure and attributes

So far, we have discussed the index method for extracting the index information of elements, attributes, and texts in a document. Moreover, we have proposed five basic query functions for finding out the index information and inferring the including relationship. Now we will describe how to use the index method and the five basic query functions for processing the higher-level user queries. Based on the previous example document, we take three examples to explain how to find out the results of query on content, structure and attribute as following. The first and second examples are combinations of content and structure query. The third one is a combination of structure and attribute query.

Example 1: Find out the title and author's name of every book whose publisher's name is "Addison-Wesley".

Step 1:
- Call Match_Text ("Addison-Wesley")
  - Return: 1 17 and 1 41
- Call Include ("publisher/name", 1, 17)
  - Return: 1 16 19 4
- Call Include ("publisher/name", 1, 41)
  - Return: 1 40 43 4

Step 2:
- Call Include ("book", 1, 16, 19, 4)
  - Return: 1 4 21 2
- Call Include ("book", 1, 40, 43, 4)
  - Return: 1 22 45 2
Step 3:
Call Included ("title", 1, 4, 21, 2)
  Return: 1 5 8 3
Call Included ("author/lastname", 1, 4, 21, 2)
  Return: 1 10 13 4
Call Included ("title", 1, 22, 45, 2)
  Return: 1 23 26 3
Call Included ("author/lastname", 1, 22, 45, 2)
  Return: 1 28 31 4 and 1 34 37 4

Step 4:
Call Match_Text (1, 6)
  Return: An Introduction to Database Systems
Call Match_Text (1, 11)
  Return: Date
Call Match_Text (1, 24)
  Return: Foundation for Object/Relational
  Databases: The Third Manifesto
Call Match_Text (1, 29)
  Return: Date
Call Match_Text (1, 35)
  Return: Darwen

In Step 1, after calling Match_Text("Addison-Wesley") function to get index information of keyword “Addison-Wesley”, the system checks to see if the keyword “Addison-Wesley” is a publisher’s name by call Include("publisher/lastname", 1, 17) and Include ("publisher/name", 1, 41) functions. The Step 2 is finding out which book includes the index information of results – 1 16 19 4 and 1 40 43 4 in Step 1 by calling Include("book", 1, 16, 19, 4) and Include ("book", 1, 40, 43, 4) functions. The Step 3 looks for what index information of “title” and “author/lastname” are included in index information of element book - 1 4 21 2 and 1 22 45 2 by calling Included("title", 1, 4, 21, 2), Included("author/lastname", 1, 4, 21, 2), Included("title", 1, 4, 21, 2), and Included ("author/lastname", 1, 4, 21, 2) functions. The last Step, the system uses the document number and the first index interval number of returned index information of Included() functions in Step 3 to extract the content of the title and author’s name for answering the user’s query by call Match_Text() function sequentially. Before the system calls the Match_Text() function, the system has to add 1 to the each first index interval number of returned index information in Step 3. These index information can be used to extract the corresponding content. For instance, the content of element title>1 5 8 3 is 1 6> An Introduction to Database Systems.

Example 2: Find out the title and publisher of every book whose author’s name is “Darwen”.
Step 1:
Call Match_Text ("Darwen")
  Return: 1 35
Call Include ("author/lastname", 1, 35)
  Return: 1 24 27 4
Step 2:
Call Include ("book", 1, 24, 27, 4)
  Return: 1 22 45 2
Step 3:
Call Included ("title", 1, 22, 45, 2)
  Return: 1 23 26 3
Call Included ("publisher/lastname", 1, 22, 45, 2)
  Return: 1 40 43 4
Step 4:
Call Match_Text (1, 24)
  Return: Foundation for Object/Relational
  Databases: The Third Manifesto
Call Match_Text (1, 41)
  Return: Addison-Wesley

The Step 1 checks to see if the keyword “Darwen” is a author’s name and the Step 2 checks which book includes the author name is “Darwen”. Step 3 finds out the index information of book’s title and publisher name and uses these information for answering the user’s query in Step 4.

Example 3: Find out every book whose publishing year is “1995”.
Step 1:
Call Match_Att ("year", “1995")
  Return: 1 4 1995
Call Include ("book", 1, 4)
  Return: 1 4 21 2
Step 2:
Call Included ("title", 1, 4, 21, 2)
  Return: 1 5 8 3
Call Included ("author/lastname", 1, 4, 21, 2)
  Return: 1 10 13 4
Call Included ("publisher/lastname", 1, 4, 21, 2)
  Return: 1 16 19 4
In Step 1, the system will check the keyword “1995” is included in which book. The Step 2 finds out the index information of book’s title, author, and publisher and uses these index information for answering the user’s query in Step 3.

4 Update method

After on user insert or remove some element of structured document, the document content and index information has to be changed. Once the structure changed, we have to do something to maintain the document content and index information integrations. Otherwise, we cannot retrieve the content correctly anymore. One of the update methods is to re-compute the index information of the document immediately. And then write the new index information back to the index information storage. This method is called Immediate Update, which can maintain the integration on index information of document and the content of document. But this way may waste too much overhead for frequent updating. Another update methods can avoid the expensive update cost and provide update index information more efficiently is called Lazy update [3]. Lazy Update use an index update table to record the index update and index transformation information, it let’s the system does not need to update the index immediately. Then, the system can select suitable time to clean up the index information. However, Jyh-Hong Tsay et al. did not consider the validation of the structured document after inserting and removing the element of structured documents.

We take advantages of Lazy Update and modified the concept of Lazy Update to solve the problem on the validation of the structured documents and let the updating of index information more efficiently. The following are our different strategies on different cases.

(1) Modifying the specific content of some element

First of all, we have to find out the specific content position of the element in TEXT list and Q-TEXT list that we want to modify. Then we use the new data to replace the old data. In this case, we only need to do this modification immediately, because the structure of whole XML document does not be changed.

(2) Removing some element structure

In this case, we will use the update table to keep the index interval of the removed element. For example, we want to remove the first author of second book of example document in Figure 4 (i.e. Date). First, we have to find out which index interval of element includes the author’s name “Date”. Next, we record it’s index information (i.e. <1, 27, 32, 3>) in the update table. Using the concept of update table a user still could issue the query after this operation, but the system needs to check that the element structure is removed from the index information lists or not before outputting the query result.

If we issue a query: Find out the title and author’s name of every book whose publisher’s name is “Addison-Wesley” (i.e. Example 1 of section 3) after the above removing operation, the system will check
to see if the index interval of result data is included in the index interval which are recorded in the update table. So the result of Example 1 doesn’t contain “Date”.

(3) Inserting some element structure

In this case, the system will insert the element structure that we want to add into the XML document into the last of relative position of document tree. Because we have to consider the validation of XML document and insert the index information of the inserted element structure into the index information lists easily.

We will describe the concept of inserting an element structure by using the following element structure in Figure 7. Assume that we will insert the element structure into the example document in Figure 4. First of all, the system has to figure out the index information of tree structure of the inserted elements, assign the one to document number, and calculate the difference of index interval numbers of the root node (i.e. 17-0=17) in the inserted element structure. The concept of insertion operation and the result document tree of insertion operation are shown in Figure 8 and Figure 9 respectively. The inserted element structure is a sibling of second book in the example document tree. So the first index interval number of the root in inserted element structure is starting form 46 and it’s level number is starting form 2. The system will add 46 to each index interval number, add 2 to each level number in the inserted element structure, add 18 (i.e. the difference of index interval numbers of root node in inserting element structure+1) to each index interval number great than 45 in the original index information lists, and then insert the index information of the inserted element structure into the last of the corresponding position of the ELEMENT, ATTRIBUTE, TEXT lists.

The new content of all lists after insertion operation are shown in Figure 10.

![Figure 7: Inserted element and structure](image)

![Figure 8: The concept of insertion operation](image)
5 Future work

So far, we have discussed the update method on the index information lists, but did not discuss how to update the XML document correspond to the changed index information lists. The reason is that we can answer user’s queries just by the index information lists, not original XML document. Furthermore, we will propose the write back strategy to handle the integration problem of the original XML document and it’s index information lists. Moreover, we will use the XML scheme for setting more data types on content of XML document on the document validation, and take the XQL or XML-QL [1] grammar to implement the system query language.

6 Conclusions

In order to perform structure queries efficiently on structured documents, we have proposed the new index method that makes the users can issue the content, structure and attribute queries on XML documents. We have shown how to handle these kinds of queries and how to use the strategies of update method for solving the update problem on element’s insertion, element’s removing and content’s modification situations.
